Abstract. The roles and impacts of black carbon (BC), an important aerosol species affecting Earth's radiation budget, are not well understood owing to lack of accurate long-term observations. To study the temporal changes in BC since the pre-industrial period, we analysed BC in an ice core drilled in northwest Greenland. Using an improved technique for BC measurement and a continuous flow analysis system, we obtained accurate and high temporal resolution records of BC particle size and mass/number concentrations for the past 350 years. Number and mass concentrations, which both started to increase in the 1870s associated with inflow of anthropogenically derived BC, reached their maxima in the 1910s–1920s and then subsequently decreased. On the basis of backward trajectory analyses, we found that North America was the dominant source region of the anthropogenic BC in the ice core. The increase in anthropogenic BC shifted the annual concentration peaks of BC from summer to winter–early spring. After BC concentrations diminished to pre-industrial levels, the annual peak concentration of BC returned to the summer. We found that anthropogenic BC particles were larger than biomass burning BC particles. By separating the BC in winter and summer, we reconstructed the temporal variations in BC that originated from biomass burning, including the period with large anthropogenic input. The BC that originated from biomass burning showed no trend of increase until the early 2000s. Finally, possible albedo reductions due to BC are discussed. Our new data provide

31   key information for validating aerosol and climate models, thereby supporting improved projections of future climate and

32   environment.

33   **1 Introduction**

34   Black carbon (BC) particles, which are emitted by incomplete combustion of biomass and fossil fuels, play important roles in

35   Earth's radiation budget and thus in climate change (Bond et al., 2013; Moteki, 2023; Matsui et al., 2022; Legrand et al., 2016).

36   In turn, changes in climate can affect emissions of BC from biomass burning through natural processes such as wildfires.

37   Global warming is considered a major cause of the recent increase in large wildfires globally that can cause serious damage to

38   ecosystems and human society (Calkin et al., 2023; Keeley and Syphard, 2021; Wang et al., 2021; Keane et al., 2008).

39   Increased occurrence of large wildfires in the future could affect Earth's radiation budget, and change the frequency at which

40   certain regions are exposed to serious hazard. Changes in fossil fuel combustion since the Industrial Revolution have changed

41   Earth's radiation budget and contributed to the warming or cooling over the past century (Shindell and Faluvegi, 2009;

42   McConnell et al., 2007; Breider et al., 2017). To understand the effects of BC on the radiation budget and of the impact of

43   climate change on BC emissions, the long-term changes in the concentrations and size distributions of BC particles should be

44   known. Data obtained since the pre-industrial period are particularly valuable because we cannot fully understand the

45   anthropogenic effects without characterizing BC in a pristine environment. The Arctic is the key region for clearer elucidation

46   of the roles of BC because the Arctic has warmed at a rate four times faster than that of the global average over the past half

47   century, leading to drastic changes such as sea ice retreat, enhanced glacier mass loss, and ecosystem changes (Rantanen et al.,

48   2022). Despite numerous studies based on observations and aerosol/climate models (e.g., Bond et al., 2013 and references

49   therein), we have only limited knowledge on BC owing to lack of accurate long-term in situ observations (Mori et al., 2019).

50   For the Arctic region, data are particularly sparse and few long-term records of BC size distribution exist.

51   Although there have been no direct observations before the past few decades, ice cores drilled in the Arctic have

52   provided long-term records of BC. Development of the Single-Particle Soot Photometer (hereafter, SP2; Droplet Measurement

53   Technologies, USA) (Stephens et al., 2003; Baumgardner et al., 2004) enabled measurements of BC in Arctic ice cores, where

54   BC concentrations are low and sample volumes are limited (McConnell et al., 2007; Zdanowicz et al., 2018; Zennaro et al.,

55   2014; Osmont et al., 2018). A continuous flow analysis (CFA) system is often used with the SP2 for high-resolution analysis

56   of ice cores (McConnell et al., 2007; Zdanowicz et al., 2018; Zennaro et al., 2014). With an SP2 attached to a CFA system,

57   McConnell et al. (2007) reconstructed BC mass concentrations in central and southern Greenland since the pre-industrial

58   period. They showed that BC concentration began a gradual rise after 1850, which was followed by rapid increase around

59   1890, a peak at around 1910, and then erratic decline through the late 1940s, followed by a sharp drop in the 1950s. They

60   attributed the increase to BC derived mainly from fossil fuel combustion in North America. Similar anthropogenic temporal

61   trends have been reported for other Greenland sites (McConnell, 2010). The BC flux records presented by McConnell (2010)

62   suggest that the anthropogenically derived increase in BC was substantially less in northern Greenland than in southern

63   Greenland, which is closer to the emission sources in North America and Western Europe. McConnell et al. (2007) also

64   reported that the greatest increase in anthropogenic BC occurs in winter. However, no BC particle size data from Greenland

65   ice cores have been published to date.

66   At Arctic sites outside Greenland, only a few ice cores have been analysed for BC. An ice core from Holtedahlfonna

67   (Svalbard) indicated that BC mass concentration started to increase after 1850 and peaked around 1910, similar to the BC

68   record of ice cores from Greenland (Ruppel et al., 2014). BC concentrations in the Holtedahlfonna core increased again

69   between 1970 and 2004, reaching unprecedented values in the 1990s. This increase is not seen in Greenland ice cores, and

70   contradicts atmospheric BC observations from Svalbard and other Arctic sites (Sharma et al., 2013), which indicate declining

71   concentrations of atmospheric BC. Ruppel et al. (2014) attributed the differences partly to the different sources of

72   anthropogenic BC affecting Svalbard and Greenland attributable to different air mass trajectories. They also suggested that

73   changes in scavenging efficiency might have affected the Holtedahlfonna BC record. An ice core from Lomonosovfonna,

74   another site in Svalbard (Osmont et al., 2018), showed gradual increase in BC during 1800–1859, followed by dramatic

75   increase from 1860. The concentrations displayed two maxima at around 1870 and 1895, before they started to decline.

76   Between 1910 and 1949, concentrations of BC were low. In contrast to the concentrations of BC in Greenland, another notable

77   increase was evident in the Lomonosovfonna core after 1940, and the concentrations were at their highest in the 1950s and

78   1960s. The BC concentrations started to decrease in the 1970s, i.e., much later than the start of the decline in Greenland. The

79   authors argued that the differences between Greenland and Lomonosovfonna are partly related to the different source regions

80   of the air masses reaching Greenland and Svalbard.

81   The differences between the Holtedahlfonna and Lomonosovfonna records might also reflect different methods used

82   for the measurement of BC mass concentration. The samples from the Holtedahlfonna ice core were filtered, and then the

83   filters were analysed for BC using a thermal–optical method (Osmont et al., 2018), whereas the Lomonosovfonna and

84   Greenland ice cores were analysed using an SP2. Uncertainties regarding the filtering efficiency (Ruppel et al., 2014) and the

85   effects of dust particles on the thermal–optical method could partly explain the differences in the long-term trends in BC

86   concentrations. Furthermore, melt–freeze cycles that commonly occur at ice coring sites in Svalbard would have affected the

87   BC concentrations (Osmont et al., 2018). Moreover, melt–freeze cycles could have agglomerated the BC particles to larger

88   sizes beyond the detection range of a standard SP2 (Osmont et al., 2018; Wendl et al., 2014). An ice core BC record from the

89   Devon Ice Cap in the Canadian Arctic was also found to differ from the records of Greenland ice cores (Zdanowicz et al.,

90   2018). Although such differences could be partly attributable to different BC source regions, melt–freeze cycles could have

91   also affected the Devon Ice Cap record. To investigate whether melt–freeze cycles did affect the derived BC concentrations,

92   we need to know the sizes of the BC particles.

93   Even for ice cores drilled at sites where summer melting seldom occurs, such as those from interior Greenland, it is

94   important to investigate the size distributions of BC particles to verify whether they are within the detection range of the SP2

95   instrument. This is because the sizes of BC particles in snow are often larger than those in the atmosphere (Schwarz et al.,

96   2013; Mori et al., 2019) and exceed the detection range of a standard SP2, which is usually between approximately 70 and 850

97   nm (Mori et al., 2019). If a large proportion of BC particles have a diameter of >850 nm, the BC mass concentrations would

98   be underestimated (Mori et al., 2019; Goto-Azuma et al., submitted). Furthermore, if an ultrasonic nebuliser, such as the

99   U5000AT (CETAC Technologies, USA), was used with a standard SP2, as was the case in most previous studies of BC in ice

100   cores (McConnell et al., 2007; Kaspari et al., 2011; Zennaro et al., 2014; Bisiaux et al., 2012a, b; Wang et al., 2015; Zdanowicz

101   et al., 2018; Du et al., 2020), the upper limit of detectable BC size would have been <850 nm (Goto-Azuma et al, submitted).

102   Because the nebulizing efficiency of this type of nebulizer varies markedly within this size range, variation in efficiency should

103   be considered when calculating accurate mass concentrations and size distributions (Ohata et al., 2013). However, this was not

104   taken into account in most previous ice core studies. It is therefore important to analyse Arctic ice cores using an instrumental

105   set-up that allows detection of BC particles with diameter of >850 nm, and also to consider the size-dependent efficiency of

106   the nebulizer. We developed a CFA system that includes a BC unit, which allows accurate high-resolution measurement of

107   concentrations and size distributions of BC particles with diameter between 70 nm and 4 μm. Using this system, we analysed

108   an ice core drilled at the SIGMA-D site in northwest Greenland. The details of this new system and its performance are

109   described in the companion paper (Goto-Azuma et al., submitted). In this study, we analysed the data and investigated the

4

110   temporal variability in concentration and size distribution of BC that originated from fossil fuel combustion and biomass

111   burning.

112   The BC detected in Arctic ice cores, together with NH_4^+ and specific organic materials (i.e., formate, levoglucosan,

113   vanillic acid, and p-hydroxybenzoic acid), has been used to reconstruct past biomass burning (Ruppel et al., 2014; Zennaro et

114   al., 2014; Grieman et al., 2017, 2018; Fischer et al., 2015; Pokhrel et al., 2020; Legrand et al., 2016). Although both BC and

115   NH_4^+ have sources other than biomass burning (Osmont et al., 2018), levoglucosan, vanillic acid, and p-hydroxybenzoic acid

116   primarily originate from biomass burning. However, the data regarding such organic materials usually have lower temporal

117   resolution compared with that of BC and NH_4^+ data owing to limitations of the measurement techniques. Furthermore, little is

118   known about their changes during atmospheric transport and post-depositional processes (Hennigan et al., 2010). Different ice

119   core proxies often show different temporal and spatial trends in biomass burning activities (Legrand and de Angelis, 1996;

120   Legrand and Mayewski, 1997; Legrand et al., 1992, 2016; Kawamura et al., 2012; Grieman et al., 2017, 2018; Rubino et al.,

121   2016; Zennaro et al., 2014). Compared with the Global Charcoal Database, which has been used widely to investigate changes

122   in biomass burning on centennial to orbital time scales (Power et al., 2010; Marlon et al., 2016), ice core proxy records usually

123   have higher temporal resolution. Even monthly or seasonally resolved continuous records of BC and NH_4^+ for the past few

124   centuries, millennia, and hundred thousand years have been derived from several Arctic ice cores, thereby allowing detection

125   of high spikes in concentration in summer attributable to large boreal forest fires in northern North America and/or Siberia

126   (Fischer et al., 2015; Zennaro et al., 2014). However, previous studies using BC as a biomass burning tracer have been

127   restricted to the pre-industrial period. This is because BC originated from fossil fuel combustion contributed greatly to the total

128   BC concentrations and obscured the temporal trends in BC related to biomass burning.

129   In this study, we reconstructed monthly resolved concentrations and sizes of BC particles in northwest Greenland

130   over the past 350 years. The BC originated both from biomass burning and from fossil fuel combustion was distinguished

131   owing to their different seasonal variability. In this paper, we discuss the temporal trends in the concentration and size of BC

132   particles originated from both sources, and we investigate the BC source regions based on backward trajectory analyses. We

133   then estimated the potential albedo reductions based on the monthly mean BC concentration data.

2 Materials and Methods

2.1 Ice core processing, analyses, and dating

A 222.7 m ice core was drilled at the SIGMA-D site (77.636° N, 59.120° W; 2100 m a.s.l.; Fig. 1) in northwest Greenland in spring 2014 (Matoba et al., 2015). The annual mean air temperature and accumulation rate at the site were estimated to be -25.6 °C and 0.23 w eq·yr^{-1}, respectively (Nagatsuka et al., 2021). The details of the ice core processing and analyses are described in the companion paper (Goto-Azuma et al., submitted to Atmospheric Chemistry and Physics); therefore, we provide only a brief summary here. The top 175.77 m of the core was divided into two vertical sections (Sections A and B) in the field. Section A was kept frozen and transported to the National Institute of Polar Research (NIPR) in Japan; Section B was cut, melted, and bottled in the field.

Figure 1: Location of the SIGMA-D site and that of other drill sites.

Down to the depth of 112.8 m in Section A, we cut quadrangular prism samples with a cross section of 34 mm × 34 mm. For the depth interval between 6.1 and 112.8 m, we analysed BC, stable water isotopes, and six elements (i.e., ^{23}Na, ^{24}Mg, ^{27}Al, ^{39}K, ^{40}Ca, and ^{56}Fe) using the NIPR CFA system. The top 6.1 m of Section A was too fragile to be analysed using the CFA system; hence, we manually cut it into segments of approximately 0.1 m. These "discrete samples" were decontaminated in a -20 °C cold room using a precleaned ceramic knife and then placed in powder-free plastic bags. They were then melted and transferred to precleaned glass and polypropylene bottles in a class 10,000 clean room. The samples in glass bottles were analysed for stable isotopes of water and BC. For the discrete samples, stable isotopes of water were analysed using a near-

151   infrared cavity ring-down spectrometer (L2120-i, Picarro Inc., USA), a high-precision vaporizer (A0211, Picarro Inc., USA),

152   and an autosampler (PAL HTC9 - xt - LEAP, LEAP Technologies, USA). The precision of determination was ±0:05‰ for

153    $\delta^{18}O$. The samples in the polypropylene bottles were analysed for six elements (i.e., ^{23}Na, ^{24}Mg, ^{27}Al, ^{39}K, ^{40}Ca, and ^{56}Fe) using

154   an inductively coupled plasma mass spectrometer (7700 ICP-MS, Agilent Technologies, USA) in a class 10,000 clean room

155   at NIPR.

156   Both the CFA samples and the discrete samples were analysed for BC using a Wide-Range SP2 (Mori et al., 2016),

157   which is a modified version of the SP2 (Droplet Measurement Technologies, USA), and a concentric pneumatic nebulizer

158   (Marin-5, Teldyne CETAC, USA). The combination of the Wide-Range SP2 and the pneumatic nebulizer enabled us to extend

159   the range of the size of BC particles analysed (70 nm < diameter < 4 μm) to beyond that of the standard SP2 (70 nm < diameter

160   < 600–850 nm). This combination and a careful calibration procedure enabled us to measure not only the concentration but

161   also the diameter of BC particles. The analytical errors of the BC mass and number concentrations were estimated to be <16%

162   (Mori et al., 2016). The reproducibility of the BC number and mass concentrations for repeated measurements was usually

163   better than 10% (Mori et al., 2019). The detection limits of the BC number and mass concentrations were approximately 10

164   counts·L^{-1} and 0.01 μg·L^{-1}, respectively.

165   Depths of Section B above 61.2 m were analysed for Na^+, K^+, Mg^{2+} and Ca^{2+}, Cl^-, NO_3^-, and SO_4^{2-} using two ion

166   chromatographs (ICS-2100, Thermo Fisher Scientific, USA) at Hokkaido University (Japan), whereas depths between 61.2

167   and 112.87 m were analysed for NH_4^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, NO_3^-, and SO_4^{2-} using two ion chromatographs (ICS-2000,

168   Thermo Fisher Scientific, USA) at NIPR. The limit of detection of Na^+ measured at Hokkaido University was 1 μg L^{-1}, whereas

169   that measured at NIPR was 0.2 μg L^{-1}. Stable water isotopes were analysed for all samples from Section B using a near-

170   infrared cavity ring-down spectrometer (L2130-i, Picarro, USA) and a high-throughput vaporizer (A0212, Picarro, USA) at

171   Hokkaido University. The precision of determination was ±0:08‰ for $\delta^{18}O$. For dating purposes, tritium concentrations were

172   measured using a liquid scintillation counter (LSC-LB3; Aloka Co. Ltd., Japan) at 0.05 m intervals for the depth interval

173   19.15–26.47 m (Nagatsuka et al., 2021).

174   Figure 2 shows the seasonal variability in Na and Na^+ concentrations, together with that in $\delta^{18}O$ (Goto-Azuma et al.,

175   submitted). Concentrations of Na and Na^+ show maxima in winter and minima in summer, whereas the $\delta^{18}O$ shows maxima

176   in summer and minima in winter (Nagatsuka et al., 2021; Legrand and Mayewski, 1997; Mosher et al., 1993). As reported in

177   the companion paper (Goto-Azuma et al., submitted), we dated Section B of the SIGMA-D core by annual layer counting

178   using mainly Na$^+$ (Nagatsuka et al., 2021). We supplementarily used Ca and δ^{18}O data when annual peaks of Na$^+$ were not

179   clearly observed. Additionally, we used a tritium peak and volcanic SO$_4^{2-}$ peaks as reference horizons (Nagatsuka et al., 2021).

180   Because the CFA data from Section B and the discrete data from Section A agreed well (Fig. 2), we adopted the chronology

181   of Section B for that of Section A. However, for the years before 1783, we made minor adjustments where high SO$_4^{2-}$ peaks

182   did not match the volcanic eruptions reported from study of other Greenland ice cores (Sigl et al., 2013). The uncertainties of

183   dating were estimated to be less than ±2 years. The CFA data covered 1653–2002 (Goto-Azuma et al., submitted), and the data

184   from the top 6.1 m covered the period 2003–2013. We divided one year into 12 months based on the assumption that the annual

185   maxima and minima of Na$^+$ concentration correspond to 1 January and 1 July, respectively (Fig. 2). Each depth interval

186   corresponding to a half year was evenly divided into six months. Using the CFA data, we calculated the annual mean and the

187   monthly mean values of the number and mass concentrations of BC particles.

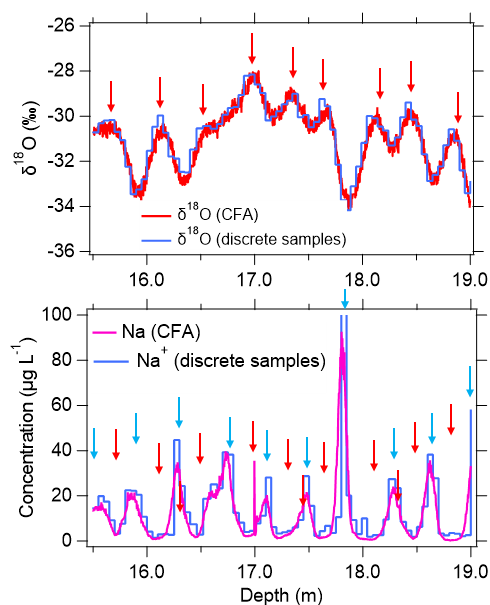

Figure 2: Concentrations of (a) δ^{18}O and (b) Na (and Na$^+$) (Goto-Azuma et al., submitted). Red and blue curves represent data obtained from CFA measurements and discrete sample measurements of the SIGMA-D core, respectively. Blue and red arrows indicate winter and summer, respectively. Winter and summer peaks were assumed to represent January 1 and July 1 of each year, respectively.

188

189

2.2 Backward trajectory analysis

To estimate the contributions of different air masses affecting the SIGMA-D and D4 sites (Fig. 1), we performed 10-day

backward trajectory analyses for the period 1958–2015. Dividing the globe into 21 regions (Fig. A1), we calculated the

contribution from each region. We used the Single-Particle Lagrangian Integrated Trajectory (HySPLIT) model developed by

the National Oceanographic and Atmospheric Administration (NOAA) (Stein et al., 2015). The initial air mass was set at three

elevations at each site (i.e., 500, 1000, and 1500 m above ground level), and the accumulated probability of the air mass in

each 1° grid cell was calculated. Assuming wet deposition of BC at the ice core sites, the air mass probability was weighted

with the local daily precipitation, i.e., if no precipitation occurred, the air mass was not considered, and vice versa. We used

ERA5 precipitation data produced by the European Centre for Medium-Range Weather Forecasts (Hersbach et al., 2020).

Details of the procedures are described in previous studies (Parvin et al., 2019; Nagatsuka et al., 2021; Nagatsuka et al., 2023).

200

3 Results and Discussion

3.1 Impacts of anthropogenic emissions on long-term trends in concentrations and sizes of BC particles

Figure 3 displays annual and decadal averages of number and mass concentrations of BC during the past 350 years. Notably,

monthly mean values could have been affected by the values of the adjacent few months, considering the resolution of the

Figure 3: Annual mean (thin curves) and decadal mean (thick curves) concentrations of BC. Red and black

curves represent mass and number concentrations, respectively.

205 CFA data (10–40 mm) estimated from signal dispersion tests (Goto-Azuma et al., submitted). Because we melted the core

206 from the bottom to the top, the data for a few months after large BC concentration peaks could have been affected. However,

207 the annual and decadal averages were unaffected by the CFA signal dispersion. Apart from sporadic sharp peaks in number

208 and mass concentrations, their background levels started to increase in the 1870s, reached their maxima in the 1910s–1920s,

209 and decreased again after the 1930s. In the 1960s, BC number and mass concentrations returned to their pre-industrial levels.

210 In the 1980s and 1990s, number concentrations were below the pre-industrial level, whereas mass concentrations were similar

211 to those of the pre-industrial level. Before 1850, the major sources of BC in Greenland were likely to have been biomass

212 burning emissions from boreal forest fires (Legrand et al., 2016; McConnell et al., 2007; Zennaro et al., 2014). The increases

213 in BC concentrations that occurred in the late 19th century to mid-20th century are likely attributable to inflow to Greenland of

214 BC of anthropogenic origin, as reported previously (McConnell, 2010; McConnell et al., 2007).

215   Direct comparison between the BC concentrations in the SIGMA-D core and those in other Greenland ice cores is

216 not strictly feasible owing to methodological differences. BC measurements in other Greenland ice cores were conducted using

217 the standard SP2 coupled with an ultrasonic nebulizer (McConnell et al., 2007; McConnell, 2010; Zennaro et al., 2014). This

218 setup allows for the measurement of BC particles with diameter of less than 600–650 nm (Goto-Azuma et al., submitted). In

219 contrast, the measurements of the SIGMA-D ice core could detect BC particles with diameter up to 4 µm. Therefore, BC

220 concentrations in other Greenland ice cores might have been underestimated during periods when the diameter of large

221 proportions of BC particles exceeded approximately 650 nm. Owing to lack of information on size distributions, the extent of

222 the underestimation for other Greenland ice cores remains unknown. As described in the companion paper (Goto-Azuma et

223 al., submitted), if the measurement method used in the previous studies had also been used for the SIGMA-D ice core, the

224 extent of underestimation would have depended on depth and hence on age. However, the general temporal trends in annual

225 mean BC concentrations at the SIGMA-D site did not change notably if BC particles with diameter of >650 nm were excluded

226 (Fig. 4). Therefore, it is informative to compare the BC concentration trends at the SIGMA-D site with those of other Greenland
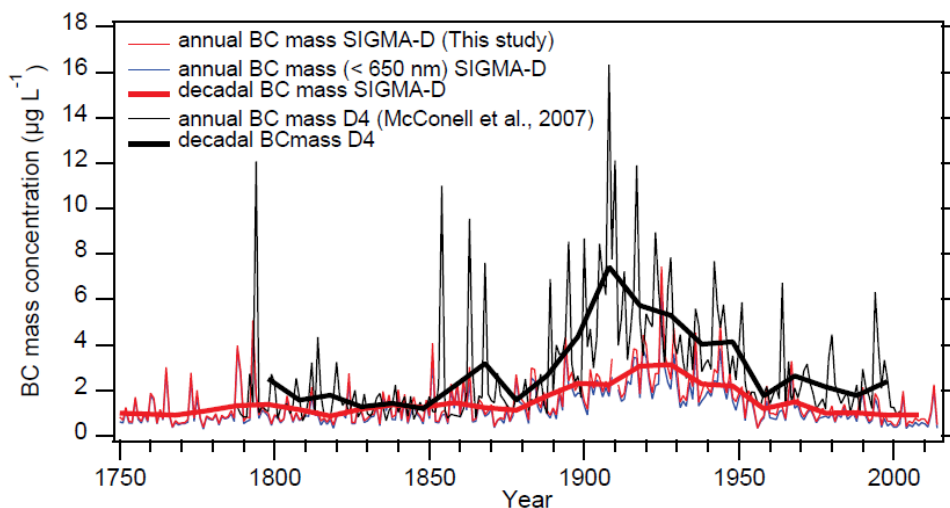

227 sites.

228

Figure 4: Annual mean (thin curves) and decadal mean (thick curves) mass concentrations of BC. Red and black curves represent BC concentrations at the SIGMA-D and D4 sites, respectively. Blue curves show annual BC concentrations for BC particles with diameter of <650 nm.

229

230   The long-term trends in BC mass concentrations at the SIGMA-D site are broadly similar to those at other ice core

231   sites in Greenland (McConnell et al., 2007; McConnel., 2010), including the D4 site. However, the SIGMA-D core shows

232   much lower anthropogenic BC concentrations, a later peak period, and later onset of the reductions in comparison with those

233   of the D4 core (Fig. 4). This is in accord with the studies by McConnel et al. (2007) and McConnel (2010), which indicate that

234   more southerly sites generally show higher anthropogenic BC concentrations, an earlier peak period, and earlier onset of the

235   decline in anthropogenic BC concentrations in comparison with those of more northerly sites. The BC emission inventories

236   for potential BC source regions indicate that emissions of anthropogenically derived BC started earlier in Europe than in North

237   America, and that the decline in anthropogenic BC concentrations started earlier in North America than in Europe or the former

238   USSR (Osmont et al., 2018). The emission inventories used by Osmont et al. (2018) were those adopted for the Coupled Model

239   Intercomparison Project phase 5 (CMIP 5; Bauer et al., 2013; Eckhardt et al., 2023; Lamarque et al., 2010). If those emission

240   inventories are reliable, then the slight difference in the temporal trends of BC concentrations would indicate that southern

241   Greenland sites (e.g., the D4 site) had been influenced mainly by anthropogenic emissions from North America, whereas

242 northern Greenland sites (e.g., the SIGMA-D site) had been influenced by anthropogenic emissions from Europe and the

243 former USSR (in addition to those from North America), as was the case for anthropogenic sulphate (Goto-Azuma and Koerner,

244 2001). However, the results of our backward trajectory study do not support this hypothesis, as discussed below.

245   The 10-day backward trajectories for the SIGMA-D and D4 sites showed no contributions of air masses from

246 Antarctica (AT), Australia and New Zealand (AUS), South America (SAM), Southeast Asia (SEA), South Asia (SA), the

247 Antarctic Ocean (ATO), South Pacific Ocean (SPO), Indian Ocean (INO), and South Atlantic Ocean (SAO). The four regions

248 of the Middle East (ME), Africa (AF), East Asia (EA), and Central Asia (CA) showed maximum contributions of <0.05%. In

249 further analyses, we omitted the above 13 regions and focused on the eight regions of Europe (EU), the Greenland Ice sheet

250 (GrIS), Russia (RUS), North America (NA), the North Pacific Ocean (NPO), North Atlantic Ocean (NAO), Arctic Ocean (AO),

251 and Iceland (IC) (Fig. 5). Of these, GrIS, AO, NA, and NAO were found to be the major sources of the air masses arriving at

252 both the SIGMA-D site and the D4 site, although only NA represents a source of anthropogenic BC emissions. Therefore, the

253 temporal trends in anthropogenic BC at both SIGMA-D and D4 appear to reflect the trend of BC emission in NA.

Figure 5: The 12 regions used for backward trajectory analyses (GrIS: Greenland Ice Sheet, NA: North America, EU: Europe, RUS: Russia, CA: Central Asia, EA: East Asia, ME: Middle East, AF: Africa, NPO: North Pacific Ocean, NAO: North Atlantic Ocean, AO: Arctic Ocean, and IC: Iceland).

254   The contributions of air masses from EU and RUS, which are regions with high levels of emission of anthropogenic

255 BC (Hoesly et al., 2018), were less than 4% and 1%, respectively, at both the SIGMA-D site and the D4 site, even in winter

256 when their contributions are at their maxima. To investigate the influence of contributions from EU and RUS in more detail,

257 we recalculated the air mass contributions by excluding GriIS and the oceanic regions of NPO, NAO, and AO where there are

258   no sources of BC emission. Although GrIS had the largest air mass contributions throughout the year and throughout the 10

259   days, we excluded it because most of the region is covered with ice and has very minor BC sources. The temporal variations

260   in the contributions from NA, EU, RUS, and IC are plotted in Fig. 6, and the probability distributions of the air masses for the

261   SIGMA-D and D4 sites are displayed in Fig. 7. In winter, when the anthropogenic input of BC is greatest at both the SIGMA-

262   D site (see Sect 3.2) and the D4 site (McConnell et al., 2007), contributions from NA are the highest at both sites. At both sites,

263   the contributions from EU and RUS increase in winter (Figs. 6 and 7) when air masses from distant sources can more easily

264   reach the Arctic (Jurányi et al., 2023). Against our expectation based on CMIP 5 emission inventories, the contributions from

265   EU were slightly greater at D4 than at SIGMA-D. The contributions from RUS were similar at both sites and comprised

266   approximately 20% of the total at most. Although backward trajectory analyses showed that contributions from EU were

267   slightly different between the SIGMA-D and D4 sites, the results suggested the opposite conclusion to that of an assumption

268   based on the regional difference in emission inventories to explain the slight differences in the temporal trend of BC at the two
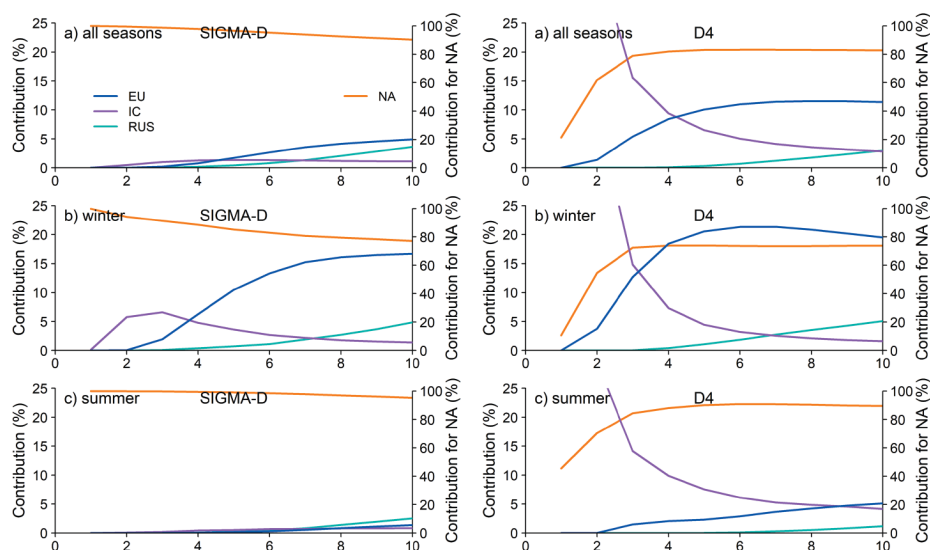

269   sites.

Figure 6: Temporal variability in contributions of air masses arriving at (left) the SIGMA-D site and (right) the D4 site from four regions: (a) averages of 12 months, (b) averages of winter months (December–February), and (c) averages of summer months (May–July). Right-hand axes indicate contributions from NA, left-hand axes indicate contributions from the other regions.
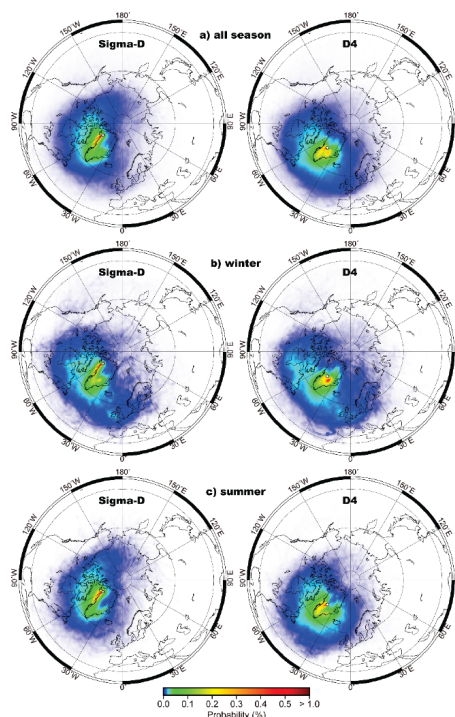

13

270

Figure 7: Probability distributions of air masses at (left) the SIGMA-D site and (right) the D4 site: (a) averages of all seasons, (b) averages of winter months (December–February), and (c) averages of summer months (May–July).

271   Notably, there are large uncertainties in emission inventories. Although the CMIP 5 emission inventories appear to

272   reproduce the temporal patterns in concentrations and fluxes of BC in Arctic ice cores better than those produced using the

273   Coupled Model Intercomparison Project phase 6 (CMIP 6) inventories, the reproduction of the magnitudes of the

274   concentrations and fluxes is better when using the CMIP 6 inventories (Eckhardt et al., 2023). A model intercomparison study,

275   which compared the modelling results obtained from 11 Earth System Models using CMIP 6 emission inventories with BC

276   records from ice cores (Moseid et al., 2022), revealed errors in European emission inventories. However, the study also showed

277   that BC concentrations in Northern Greenland ice cores reflected European emissions, contradicting our backward trajectory

278   analyses. It should be also noted that backward trajectory analyses are unable to capture the contributions of air masses

279   transported through the upper troposphere (Nagatsuka et al., 2021), which could be important when estimating the

280   contributions from distant sources. Currently, we are unable to explain the slightly different temporal trends in the BC records

14

281 from different ice cores in Greenland. Further elucidation of this topic will require additional modelling studies constrained by

282 accurate BC records from Greenland ice cores.

283   Figure 8 displays decadal mean mass and number size distributions of BC for different periods with different

284 anthropogenic inputs. We assumed that the mass size distribution follows a Gaussian distribution and thus we estimated the

285 mass median diameter (MMD), which is one of the measures of a BC size distribution. The decadal mean MMD was 226 nm

286 in the pre-industrial period of 1783–1792. It increased to 325 nm in the peak anthropogenic period of 1913–1922, and

287 subsequently decreased to 302 nm in 1993–2002 and 278 nm in 2003–2012. Number size distributions did not show noticeable

288 temporal change. To investigate the temporal changes in BC size distribution, we used the average mass of BC particles (mBC)

289 in addition to the MMD. The parameter mBC can be calculated by dividing the mass concentration by the number concentration.

290 Figure 9 shows the annual and decadal mean mBC and decadal mean MMD, together with the annual and decadal mean BC

291 mass concentrations. Of the two size parameters, mBC is easier to calculate than MMD; hence, it can be used to investigate

292 changes with high temporal resolution. Both the annual mean mBC and the decadal mean MMD started to increase in the

293 1830s and peaked in the 1910s–1920s, when the mass and number concentrations of BC were at their maxima. The peak values

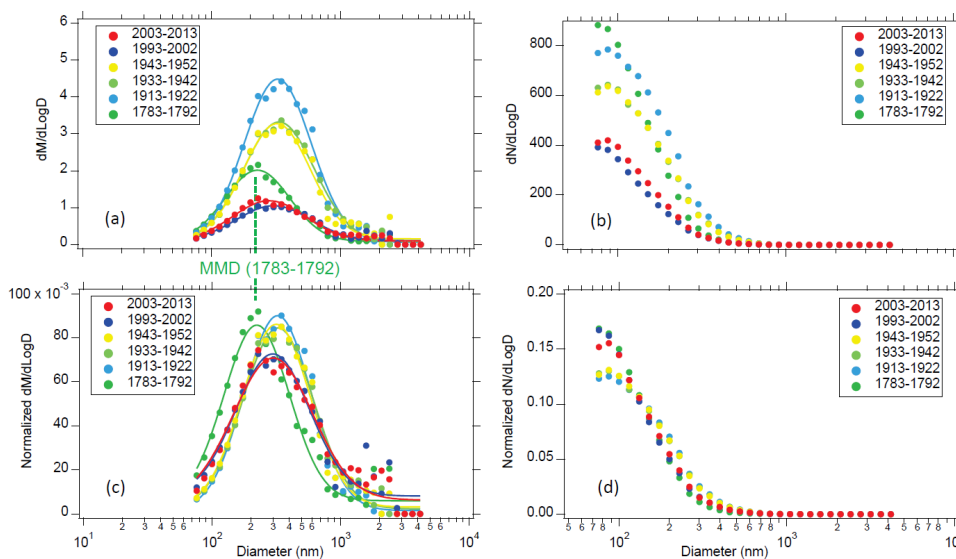

Figure 8: Temporal changes in decadal mean size distributions of BC particles: (a) and (b) non-normalized mass and number size distributions, respectively, and (c) and (d) normalized mass and number size distributions, respectively. Dotted line in (a) indicates the mass median diameter (MMD) for the period 1783–1792.
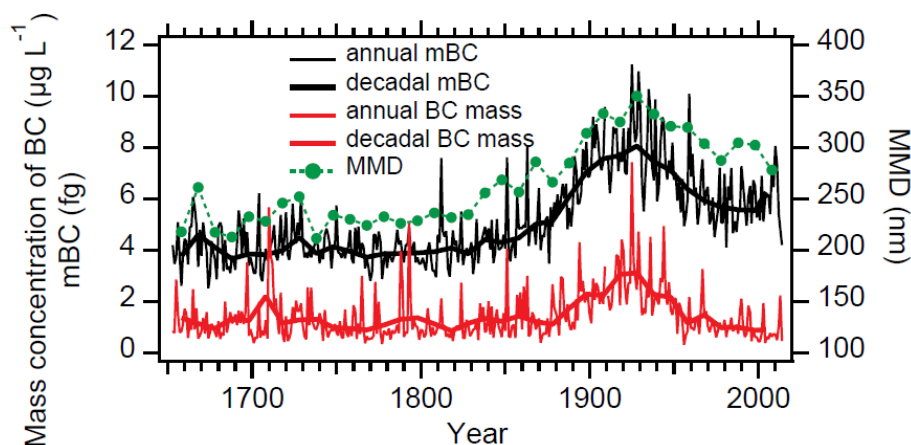

Figure 9: Annual and decadal mean mBC (black) and decadal mean MMD (green), together with annual and decadal mean BC mass concentration (red). Thin and thick solid lines denote annual and decadal means, respectively.

294   of MMD and mBC were approximately twice and 1.5 times, as high as the corresponding pre-industrial values, respectively.

295   Anthropogenically derived BC particles that arrived in northwest Greenland appear to have been larger than BC particles of

296   biomass burning origin. This is contrary to our expectation because it has been reported that the sizes of BC particles from

297   biomass burning are larger than those from anthropogenic emissions near the sources (Bond et al., 2013). In the 1920s or 1930s,

298   MMD and mBC both started to decrease, as did the mass and number concentrations of BC particles. However, in contrast to

299   BC concentrations, neither MMD nor mBC returned to their pre-industrial levels; instead, they remained approximately 1.3

300   and 1.5 times higher than their pre-industrial levels, respectively. We also notice that the start of the increases in mBC and

301   MMD appear to have occurred earlier than the increases in mass and number concentrations of BC by 30–40 years.

302

303   **3.2 Temporal changes in seasonal variations in concentrations and sizes of BC particles**

304   Figure 10 compares the monthly mean BC mass concentrations in three periods: the pre-industrial period, the period with high

305   anthropogenic input, and recent years when concentrations decreased and returned to pre-industrial levels. Changes are evident

306   in the seasonality of BC concentrations with respect to Na concentrations, which peak in winter. As reported by McConnell et

307   al. (2007) in relation to the D4 core, BC concentrations peaked in summer in the pre-industrial period, whereas they peaked in

308   late-winter to early spring during the peak industrial period. Figure 10 also indicates that in recent years after the BC

309   concentrations returned to their pre-industrial levels, the peaks once again occurred in summer. During the transition period

310   between the pre-industrial and the peak anthropogenic periods, and that between the peak anthropogenic period and recent

311   years, concentrations show complex seasonal variability. For example, in some years, peaks occurred in both summer and

312   winter/early spring, whereas seasonal peaks were obscured or summer peaks and winter/early spring peaks appeared alternately

313   in other years.

314
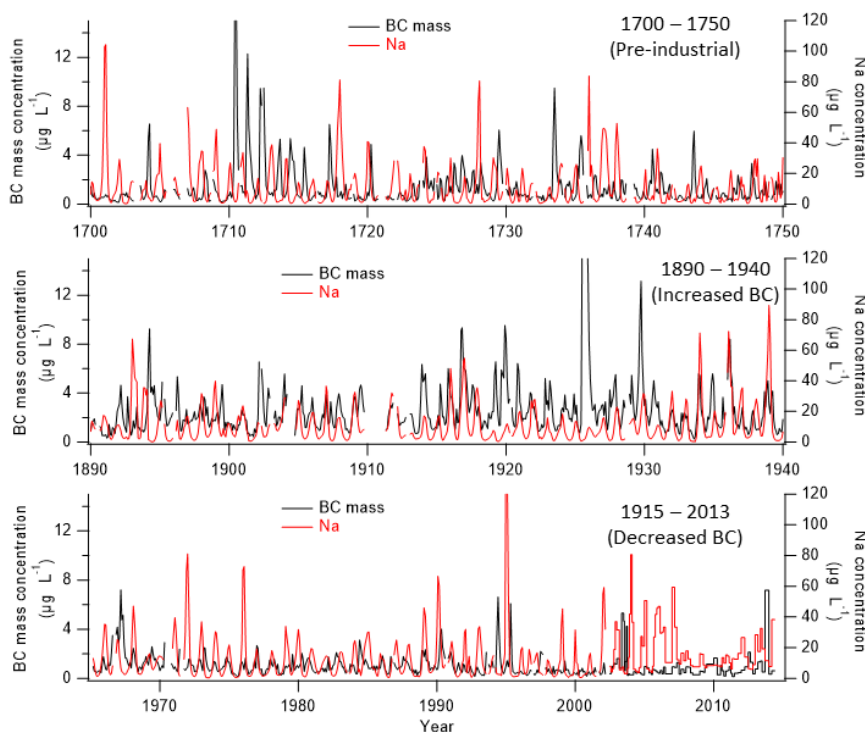

Figure 10: Monthly mean BC mass concentrations and Na concentrations in three periods calculated from the CFA data, with the exception of 2003–2013 (concentrations for this period are raw data from the discrete samples that were analysed with monthly–bimonthly resolution).

315   To examine the general temporal trends in seasonal variations in BC mass concentrations, we plotted 20-year averages

316   of BC mass concentrations in each month for the years 1653–1992 and we plotted 10-year averages for 1993–2002 (Fig. 11).

317   Up until the 20-year period of 1853–1872, BC mass concentrations were elevated from March to September, peaking in the

17

318   late-spring to summer months (i.e., May–July). After the 20-year period of 1853–1872, BC concentrations in autumn to spring

319   increased and became dominant. During the first half of the 20th century, BC mass concentrations peaked in the winter months

320   of December and January. The autumn to spring increases in BC concentrations are likely attributable to inflow of

321   anthropogenic emissions (McConnell et al., 2007). The seasonality of the anthropogenic BC at SIGMA-D is consistent with

322   that of the present-day atmospheric BC observations at Arctic sites such as Alert (Canadian high Arctic), Ny-Alesund

323   (Svalbard), Barrow (Alaska), and a Greenland coastal site (Sharma et al., 2006, 2019; Gong et al., 2010; Qi and Wang, 2019;
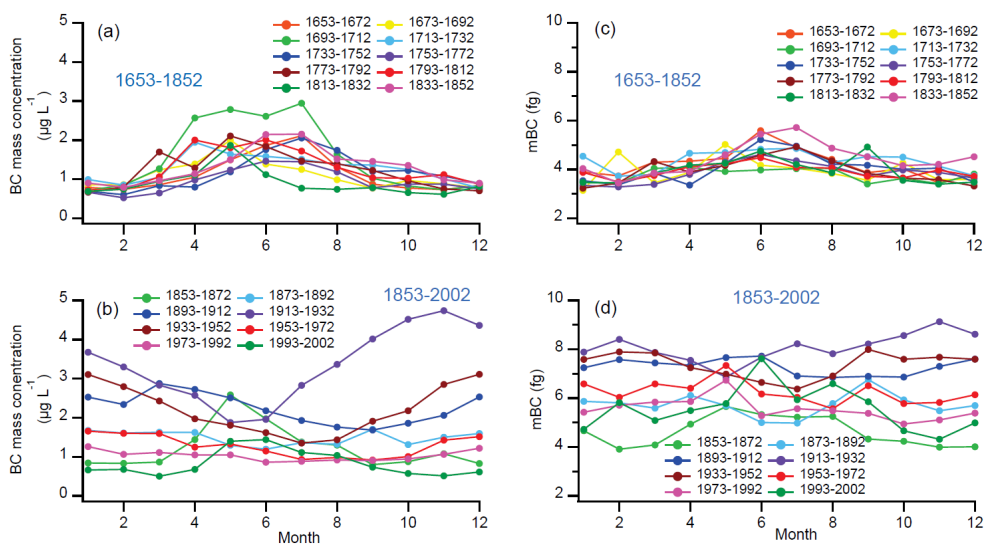

324   Massling et al., 2015).

Figure 11: Twenty-year averages of (a) and (b) BC mass concentrations and (c) and (d) mBC in each month for the years 1653–1992 and the 10-year averages for 1993–2002.

325

326   After the 20-year period of 1913–1933, when the anthropogenic input was at its maximum, the autumn to spring

327   concentrations decreased. During 1993–2002, the BC mass concentration peaked in summer again. The recent seasonality of

328   BC at the SIGMA-D site is the same as that observed at other Greenland ice-coring sites, including EGRIP (Du et al., 2020)

329   and Summit (Fig. 1) (Schmeisser et al., 2018), but it differs from that of atmospheric observations in the Arctic (including

330   Greenland), where BC concentrations peak in winter/early spring (Sharma et al., 2006, 2019; Gong et al., 2010; Qi and Wang,

331   2019; Massling et al., 2015). Although we do not present the results for BC number concentrations, they showed seasonal

332 variations similar to those found in mass concentrations. The influence of anthropogenic emissions in the recent two decades

333 appears to be much lower at the ice coring sites of SIGMA-D, EGRIP, and Summit, located at elevations of >2000 m a.s.l., in

334 comparison with that at atmospheric observation sites located near sea level where anthropogenic emissions remain dominant.

335 At the high-elevation sites on the GrIS, concentrations of BC from biomass burning have exceeded those associated with

336 anthropogenic emissions since the late 20th century, which is likely attributable to reduced emissions of anthropogenically

337 derived BC, primarily in NA and secondarily in EU (McConnell, 2010; McConnell et al., 2007; Moseid et al., 2022).

338 To understand the general temporal trends in seasonal variations in BC size, we plotted 20-year averages of mBC

339 in each month for the years of 1653–1992 and we plotted 10-year averages for 1993–2002 (Fig. 11). Up until the 20-year

340 period of 1853–1872, mBC peaked in spring to the summer months (May–July) in most of the 20-year periods and it never

341 peaked in the winter months. After the 20-year period of 1873–1892, mBC in autumn–spring increased and its seasonality

342 became obscured. After the peak anthropogenic period of 1913–1933, mBC in autumn–spring decreased. During 1993–2002,

343 mBC once again peaked in summer. We see similar temporal trends in Fig. 12, i.e., both MMD and mBC showed higher values

344 in summer in the pre-industrial period. This seasonality would indicate that the sizes of BC particles originated from biomass

345 burning are greater in summer than in winter. The winter and summer values started to increase in the 1830s–1840s with larger

346 rates of increase for winter values. Winter and summer values both peaked in the 1910s–1940s and subsequently decreased,

347 with similar rates for winter and summer. During the peak anthropogenic period, the summer and winter values were close,

348 which obscured the seasonality in BC particle size (Fig. 11(b)). The winter values became lower than the summer values in

349 1993–2002. Larger BC particles in winter in the anthropogenic period support the argument that BC particles deposited at

350 SIGMA-D were larger when originating from anthropogenic emissions than when associated with biomass burning.

351 In the pre-industrial period, biomass burning would have been the predominant source of BC. Backward trajectory

352 analyses (Figs. 6 and 7) indicate that boreal forest fires in NA would be the primary sources of BC in summer at both the

353 SIGMA-D site and the D4 site. Although the contributions of air masses from RUS are very small, especially in summer (<3%

354 at SIGMA-D; <1% at D4), Siberia has also been proposed as a potential source of pyrogenic aerosols to Greenland (Zennaro

355 et al., 2014). A recent study using the CAM-ATRAS global climate–aerosol model (Matsui et al., 2022) showed that Siberia

356 has made the largest contribution to BC concentrations found in the recent Arctic snow, although the contribution to Greenland

357 snow specifically has not been reported. We speculate that biomass burning in Siberia could be a secondary source of BC at

358 the SIGMA-D site in summer because the backward trajectory analyses showed that air masses originated from Siberia (Fig.

19

359   7). In winter, the boreal forests in NA and Siberia are covered with snow and thus there is little contribution of BC from boreal

360   forest fires (Bond et al., 2013). However, BC concentrations are not zero, even in winter. Biomass burning in lower latitudes

361   (Zennaro et al., 2014) could be a source of BC in winter, and the smaller sizes of BC particles in pre-industrial winter periods

362   suggest long-range transport of BC that supports this assumption.

363
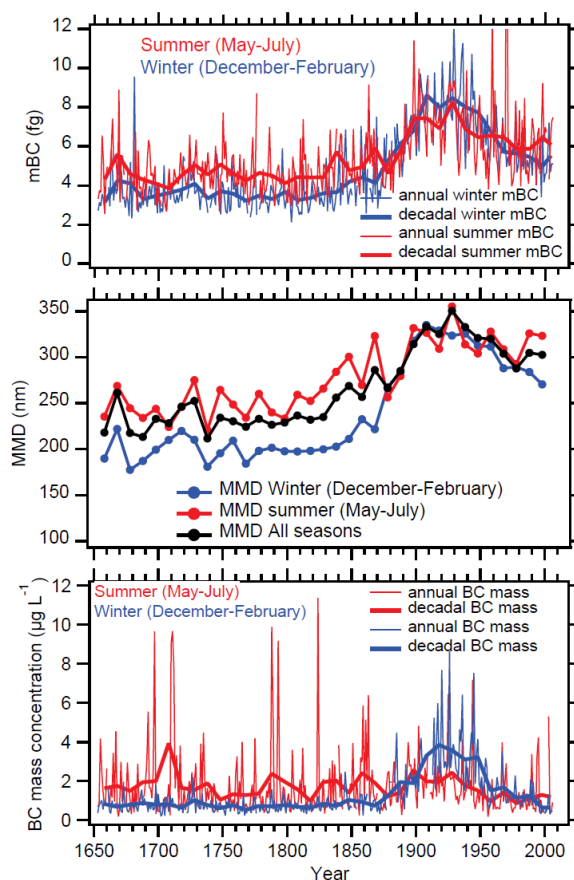

Figure 12: (a) Annual and decadal means of winter (December–February) and summer (May–July) mBC, (b) decadal means of winter, summer, and all-season (January–December) MMD, and (c) annual and decadal means of winter and summer BC mass concentrations. In all panels, thin and thick solid lines denote annual and decadal means, respectively. Blue, red, and black curves denote winter, summer, and all-season means, respectively.

364   **3.3 Historical changes in BC originated from biomass burning**

365   Figure 13 presents monthly mean BC mass concentrations for the past 350 years, together with NH_4^+ concentrations.

366   Occasional high peaks in summer likely originated from large boreal forest fires, mainly in NA but with possible additional

367   contributions from Siberia. Many of the high BC peaks in summer coincide with high NH_4^+ concentration peaks in summer,

368   which originate from large boreal forest fires (e.g., Legrand et al., 2016). Table A1 lists the biomass burning events

369   distinguished in the record of the SIGMA-D ice core, and in other ice cores and the surface snow of Greenland. The events

370   distinguished in the SIGMA-D core were defined using BC mass concentration peaks and NH_4^+ concentration peaks. For BC,

371   peaks exceeding the summer (May–July) averages for 350 years + 2σ or 3σ were selected, whereas for NH_4^+, summer peaks

372   exceeding the annual averages for 350 years + 2σ or 3σ were selected. If a BC or NH_4^+ summer peak in the SIGMA-D core

373   with a concentration between the average + 1σ and 2σ was found in the same year as when a large biomass burning event was

374   recorded at other Greenland sites, we also selected that peak as a biomass burning event. If the year of a biomass burning event

375   reported by previous studies agreed with that in the SIGMA-D core to within ±2 years, taking account of dating errors in

376   different ice cores, we assumed that the record in the different cores reflected the same event. In Fig. 13(b), we marked only

377   those events exceeding the average + 3σ. Most of the marked events (peaks in 1655, 1665, 1697, 1710, 1711, 1712, 1733,

378   1788, 1793, 1824, 1851, 1859, 1863, 1925, and 1944) occurred in May, June, or July; however, those in 1789, 1812, and 1894

379   occurred in April, the one in 1773 occurred in September, and the one in 1929 occurred in August. The peaks in 1925 and

380   1944 occurred in May and June, and we assumed that they originated from large biomass burning events. Nevertheless, we

381   could not abandon the possibility that these summer peaks might have been affected by large peaks in the preceding winters

382   owing to signal dispersion in the CFA system.

383   Most of the large events with BC concentrations that exceeded the average + 3σ were also recorded in boreal forest

384   fire records reconstructed from BC, NH_4^+, or levoglucosan concentrations in other Greenland ice cores (Table A1). The high

385   BC concentration peaks in the summers of 1665, 1710, 1711, 1712, 1812, and 1824, accompanying high NH_4^+ peaks, and the

386   high BC peak in 1859 have not been reported previously. The high NH_4^+ concentration peaks in 1675, 1690, and 1750 have

387   no corresponding BC peaks in April, May, June, July, or August, while those in 1675, 1710, 1712, 1715, and 1761 do have

388   corresponding BC peaks. As for the NH_4^+ concentration peak in 1690, the summer BC data were missing and therefore

389   comparison was not possible. Although Keegan et al. (2014) argued that the high summer BC concentrations in 1889 and 2012

390   found at Summit were associated with widespread melt events in Greenland, no high BC concentration peaks were found in

391   1889 or 2012 at the SIGMA-D site. As shown in Fig. 13 and Table A1, some of the large biomass burning events recorded in
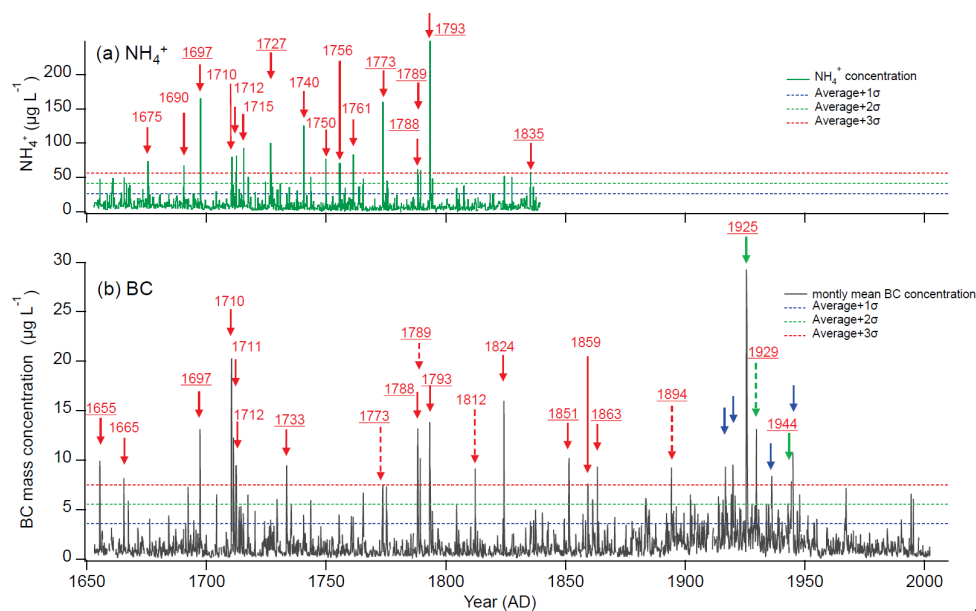

Figure 13: NH$_4^+$ concentrations: (a) raw data and (b) monthly mean BC mass concentrations (calculated from CFA data. Red arrows in (a) show years when concentrations exceeded the average + 3σ in summer. Solid and broken arrows in (b) show years when concentrations exceeded the summer (May–July) average + 3σ in summer (May–July), and in spring or autumn months (April, August, and September), respectively. Blue arrows in (b) show years when concentrations exceeded the summer average + 3σ in winter. Solid and broken green arrows in (b) show years when concentrations exceeded the summer (May–July) average + 3σ in summer (May–July), and in spring or autumn months (April, August, and September), respectively, but those that might have been affected by winter peaks. Underlining denotes years when biomass burning events were also recorded in other Greenland ice cores/surface snow samples within 2 years. Dotted lines in (a) denote the concentration average over 350 years + 1σ (blue), + 2σ (green), and +3σ (red). Dotted lines in (b) denote summer (May–July) concentration average over 350 years + 1σ (blue), + 2σ (green), and +3σ (red).

392   other Greenland ice cores were not recorded in the SIGMA-D core, and vice versa. There are two possible reasons for this: (1)

393   different ice core sites are not always on the transport pathways of BC from boreal forest fires (Legrand et al., 2016), and (2)

394   wind scour at a site can remove snow containing high concentrations of BC. Despite the minor regional differences within

395   Greenland, most of the large BC concentration peaks caused by large biomass burning events were recorded widely across

396   Greenland. This indicates that high BC concentration peaks could be used to synchronize different ice cores in Greenland as

397   reference horizons for dating, as is usually carried out with volcanic sulphate peaks and their signatures detected by

398   DEP(dielectric profiling) and ECM (electrical conductivity measurement) peaks (Rasmussen et al., 2008; Sinnl et al., 2022).

399   The numbers of large biomass burning events in each 10 years are plotted in Fig. 14 using different definitions of a

400   "large" event. Figure 14(a) displays the numbers of months with mass concentrations in summer (May–July) exceeding the

401   summer average + 1σ, 2σ, and 3σ; Fig. 14(b) displays the number of months with number concentrations in summer exceeding

402   the summer average + 1σ, 2σ, and 3σ. Because large events in April, August, and September were not counted to avoid the

403   potential for impact of anthropogenic BC, there would be minor underestimation of the number of large events. Although the

404   frequency of large events differs slightly between the different definitions, the general tendency is consistent. Large events

405   tended to be more frequent around the 1710s, 1790s, 1850s, 1900s, and 1950s. Moreover, there is no obvious trend of increase

406   up to the decade 1993–2002. To study the historical trends in concentrations of BC originated from biomass burning, we

407   calculated the decadal averages of BC mass and number concentrations for each month (Fig. 15). During the pre-industrial

408   period, both mass and number concentrations were stable in the winter months (December–February), whereas they showed

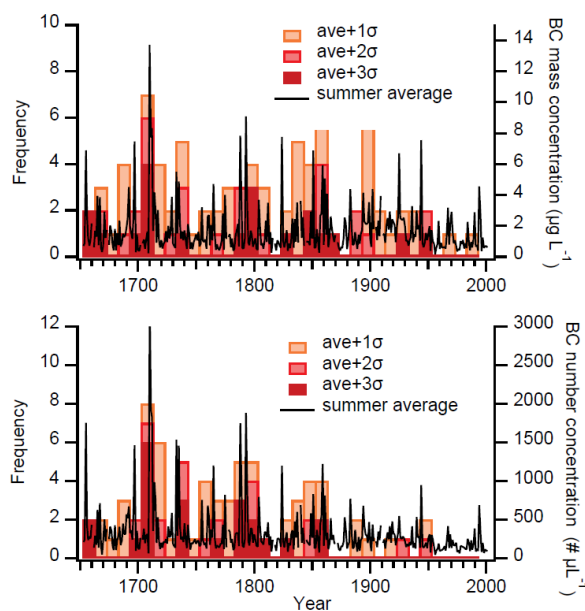

Figure 14: Frequency of large biomass burning events. Black curves denote summer (May–July) averages of BC concentrations. Bars show frequency of BC summer peaks in each decade exceeding the average + 1σ, 2σ, and 3σ. (a) Mass concentrations of BC were used to define peaks. (b) Number concentrations of BC were used to define peaks.

409   large inter-decadal fluctuations in spring to autumn months (March–November). The fluctuations appear largest in spring–

410   summer (April–July). Generally, the period of April–July is likely when the occurrence of large boreal forest fires increases

411   in NA (Whitman et al., 2018). The sporadic nature of the frequency of occurrence of large boreal forest fires would explain

412   the large fluctuations.

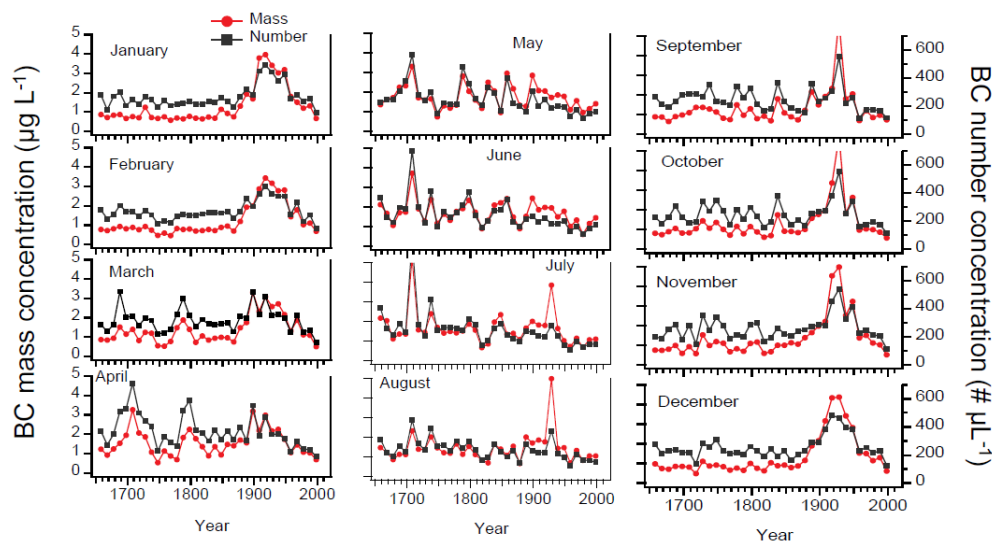

Figure 15: Decadal averages of BC mass (red) and number (black) concentrations for each month.

413   Since the 1870s, when anthropogenic BC started to influence the SIGMA-D site, BC mass and number concentrations

414   in September–April increased, as discussed in Sect. 3.3; however, there was little increase during the spring–summer months.

415   Although large inter-decadal variability in concentrations during spring–summer obscured the temporal trends in spring–

416   summer concentrations (Fig. 11), the general temporal trends are more apparent in Fig. 15. At the SIGMA-D site, we see slight

417   trends of reduction in BC mass and number concentrations during spring–summer. Analysis of Fig. 14 also suggests that the

418   frequency of large boreal forest fires in NA showed a slight trend of reduction over the past 350 years until the most recent

419   decade (1993–2002). However, this trend has not been reported by previous studies on other ice cores from Greenland, partly

420   owing to the different periods covered, the different temporal resolution of the analysis methods, and the different fire proxies

421   used (Zennaro et al., 2014; Legrand et al., 2016; Parvin et al., 2019; Savarino and Legrand, 1998; Whitlow et al., 1994). Most

422   previous studies used NH_4^+ as a fire proxy, with occasional use of levoglucosan and other organic materials; only a few studies

423   have used BC as a fire proxy for pre-industrial periods (Zennaro et al., 2014).

24

424   Since the 1950s, data on the area burned and the number of forest fires in Canada have become available (Hanes et

425   al., 2018; Skakun et al., 2021). The SIGMA-D record does not appear to trace the Canadian forest fire database. Air masses

426   arriving at the SIGMA-D site might not have passed over Canada during periods of large forest fires. Large uncertainties in

427   fire data might also explain the disagreement. There are also large uncertainties and regional variability in sedimentary charcoal

428   fire records (Marlon et al., 2012, 2013; Power et al., 2013). However, our results are consistent with the charcoal data from

429   western NA, which show general decline in biomass burning since 1500, with a relatively enhanced fire period in the mid-19th

430   century (Power et al., 2013). The biomass burning emission inventories for CMIP 6 also have large uncertainties (van Marle

431   et al., 2017). Therefore, much more work is needed on the reconstruction of past biomass burning using ice cores.

432

3.4 Impacts of BC on the ice sheet albedo

434   McConnell et al. (2007) calculated the quantitative impacts of BC in snow on radiative forcing during early summer using BC

435   concentration from D4 ice core and the Snow, Ice, and Aerosol Radiative (SNICAR) model (Flanner et al., 2007), assuming

436   an effective snow grain radius of 100 μm. They estimated the radiative forcing of 1.02 Wm^{-2} during the peak 5-year period

437   from 1906 to 1910, which is a fivefold increase from preindustrial conditions. However, the radiative forcing of BC in snow

438   varies depending on both the assumed solar irradiance and snow grain size. Then, we calculated the possible albedo reduction

439   due to BC at the SIGMA-D site from the monthly mean BC mass concentration data obtained in this study (Fig. 16) using a

440   physically based snow albedo model (Aoki et al., 2011). As the snow albedo reduction rate due to light absorbing particles is

441   enhanced with an increase of snow grain size (Wiscombe and Warren, 1980), we assumed two effective snow grain radii r_s =

442   50 μm and 1000 μm, corresponding to new snow (defined as 'precipitation particles' according to Fierz et al., 2009) and old

443   melting snow (defined as 'melt forms' according to Fierz et al., 2009) (Wiscombe and Warren, 1980) for clear sky and cloudy

444   sky (overcast) conditions. The albedo reductions under the cloudy sky are 20-48% larger than those under clear sky. These

445   increases are related to the following two factors: 1) the visible albedo depends on BC concentration more strongly than the

446   near infrared albedo (Wiscombe and Warren, 1980); 2) the visible spectral fraction in solar irradiance at the snow surface

447   under cloudy sky is larger than that under clear sky (Aoki et al., 1999). Thus, the albedo reduction due to BC under cloudy sky

448   is enhanced more than clear sky.

449   Figure 16 demonstrates that the albedo reduction in case of new snow is consistently less than 0.01, even at the

450   maximum value for cloudy conditions in August 1925 (Fig. 16a). In contrast, for old melting snow, the albedo reduction
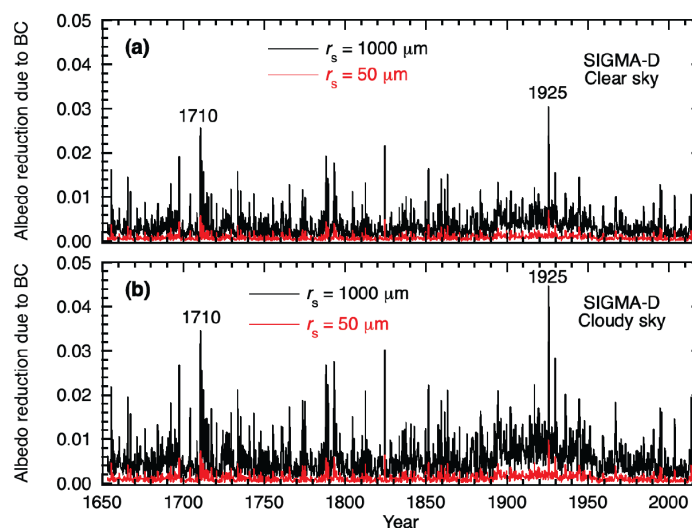

Figure 16: Temporal variation of albedo reduction for (a) clear sky and (b) cloudy sky conditions, calculated from monthly mean BC mass concentrations, for two effective snow grain radii: r_s = 50 μm (representing new snow, indicated by the red line) and r_s = 1000 μm (indicating old melting snow, shown by the black line). The albedo reduction values are calculated for solar zenith angle at local solar noon on the 15th of each month, excluding the polar night period from November to February. The maximum albedo reduction is simulated in 1925 and followed by 1710.

451 frequently exceeds 0.01 for both sky conditions (Fig. 16b). The maximum albedo reduction for cloudy conditions is 0.045 (r_s

452 = 1000 μm) and 0.0098 (r_s = 50 μm) in August 1925, followed by the values of 0.034 (r_s = 1000 μm) and 0.0074 (r_s = 50 μm)

453 in July 1710. The averaged albedo reduction for the overall period of 1650-2014 is 0.0031 (r_s = 1000 μm) and 0.0007 (r_s = 50

454 μm) for clear conditions, and 0.0054 (r_s = 1000 μm) and 0.0011 (r_s = 50 μm) for cloudy conditions. During the anthropogenic

455 concentration peak period of 1913-1933, the average albedo reduction increases to 0.0056 (r_s = 1000 μm) and 0.0012 (r_s = 50

456 μm) for clear conditions, and 0.0089 (r_s = 1000 μm) and 0.0019 (r_s = 50 μm) for cloudy conditions.

457   Warren et al. (2019) described that a BC concentration of 20 parts per billion in weight can cause broadband snow

458 albedo reductions of 1-2%. They also noted that for a typical daily average solar irradiance of 400 W m^{-2} in the Arctic during

459 late spring and early summer, a 1% albedo reduction can lead to a positive forcing of 4 W m^{-2} locally, similar to the forcing

460 caused by doubling CO_2. Our calculation results indicate that a 1% of reduction in albedo can occur at numerous local spike-

461 like peaks for r_s = 1000 μm including the recent several decades after 1950. During the anthropogenic concentration peak

462   period (1913-1933), the average albedo reduction approaches 1% (0.0089) for r_s = 1000 μm under cloudy sky conditions.

463   Consequently, our simulations suggest that the amount of albedo reduction remains relatively small as long as new snow

464   conditions are maintained. However, if the surface snow grains are the size of old melting snow, which would have occurred

465   during summer months at the SIGMA-D site, the extent of albedo reduction becomes non-negligible.

466

467   **4 Conclusions**

468   We analysed the record of BC over the past 350 years in the SIGMA-D ice core, which was drilled in northwest Greenland.

469   The improved technique for BC measurement (Mori et al., 2016) and the CFA system built at NIPR allowed us to reconstruct

470   high temporal resolution records of the sizes and concentrations of BC particles. Notably, this study marks the first

471   reconstruction of temporal changes in BC size since the pre-industrial period.

472   The number and mass concentrations of BC started to increase in the 1870s owing to anthropogenic input. The

473   concentrations reached their maxima in the 1910s–1920s, following which they decreased. By the 1960s, BC concentrations

474   had reduced to levels close to or lower than those of the pre-industrial period. The trend of anthropogenic BC at the SIGMA-

475   D site was generally similar to that reported previously for other ice core sites in Greenland, albeit with slight differences.

476   Backward trajectory analyses suggest that the major anthropogenic emission source that affected the SIGMA-D site was NA.

477   However, the backward trajectory analyses did not clearly explain the slight difference in the temporal trends of BC between

478   the SIGMA-D site and the more southerly site D4. Anthropogenic BC was transported to the SIGMA-D site mainly in the

479   winter half of the year, which was deduced by the changes in the seasonality of BC concentrations. The backward trajectory

480   analyses produced consistent results, showing greater contributions from air masses from the industrial regions in NA and

481   EUR in winter.

482   Pre-industrial BC concentrations peaked in summer. In association with increased anthropogenic input,

483   concentrations increased in winter to early spring, which shifted the annual peak in concentration to winter–early spring. When

484   the anthropogenic input started to decline in the 1930s, concentrations in winter–early spring also decreased, which changed

485   the seasonality of BC concentrations; by the 1990s, BC concentrations peaked in summer once again. This suggests that the

486   major sources of BC in recent years were not anthropogenic emissions but biomass burning. At the SIGMA-D site, BC

487   originated from anthropogenic emissions made only a minor contribution to the BC concentrations in the summer months

488   throughout the past 350 years. This enabled us to examine the temporal variability in biomass burning throughout the past 350

489   years, especially after the increase in anthropogenically derived BC, which is a topic that has not been addressed by previous

490   studies on BC data from other ice cores in the Arctic.

491   The size distributions of BC particles have also changed owing to anthropogenic impact. Both MMD and mBC started

492   to increase around the 1830s or 1840s, peaked in the 1910s–1940s when BC concentrations were at their maxima, and started

493   to decline after the 1940s. Increases in MMD and mBC accompanying the increase in BC concentrations suggest that the

494   diameter of BC particles deposited over northwest Greenland were generally larger for anthropogenic BC than for biomass

495   burning BC. The seasonality of MMD and mBC also changed, accompanying the concentration changes. However, in contrast

496   to BC concentrations, neither MMD nor mBC returned to their pre-industrial values; instead, they remained at higher values

497   in the 1960s–2000s.

498   Pre-industrial BC would have originated mainly from biomass burning. During the winters (December–February) of

499   the pre-industrial period, decadal averages of monthly mean mass and number concentrations were stable, and the sizes of BC

500   particles were smaller than those in summer. This indicates that BC in pre-industrial winters originated from biomass burning

501   in low latitudes where there was no snow cover in winter, and that biomass burning in low latitudes that affected Greenland

502   showed little change during the pre-industrial period. After the inflow of anthropogenic BC started, it became difficult to

503   distinguish biomass burning BC from anthropogenic BC in winter, making it difficult to discuss the temporal changes in BC

504   originated from low-latitude biomass burning in winter. However, we could discuss the temporal changes in boreal forest fires

505   that occur mainly in summer, the season with minimal anthropogenic input.

506   Sources of pre-industrial BC were likely boreal forest fires primarily in NA. We investigated the temporal trend in

507   the decadal frequency of large boreal forest fire events using high summer peaks of number and mass concentrations of BC.

508   We found no obvious trend of increase in the decadal frequency of large boreal forest fires until the decade of 1993–2002.

509   Furthermore, we found no trends of increase in the decadal averages of monthly mean mass and number concentrations in

510   summer during the past 350 years; we even found a trend of decrease for number concentrations. Although recent large fire

511   events in NA are attributed to global warming (Brown et al., 2023), the effects of global warming do not seem to have left

512   clear imprint in Greenland until the early 2000s. Therefore, we need further investigations using more recent ice core records

513   of BC.

514   We analysed the temporal variation of potential albedo reduction due to BC at the SIGMA-D site during the past 350

515   years using a physically based snow albedo model. Albedo reductions under the assumption of consistently new snow grain

516   size remained below 0.01, even at the peak BC concentration in 1925. Conversely, under the assumption of old melting snow

517   grain size, the albedo reduction frequently exceeded 0.01. Our calculation results reveal that a 1% of reduction in albedo can

518   occur at numerous local spike-like peaks in the case of old melting snow, including the recent several decades after 1950.

519   During the peak period of anthropogenic concentrations (1913-1933), the averaged albedo reduction approaches 1% for old

520   melting snow cases. Consequently, our simulations suggest that the magnitude of albedo reduction remains relatively small as

521   long as new snow conditions are maintained. However, if the surface snow grains are the size of old melting snow, the amount

522   of albedo reduction becomes non-negligible.

523   Our new high temporal resolution records of BC concentrations and sizes could contribute to evaluation of the impacts

524   of both anthropogenically derived and biomass burning originated BC on Earth's radiation budget, albedo, BC–cloud

525   interactions, and therefore BC–climate interactions. They could also contribute to validation of emission inventories, and

526   aerosol and climate models. High temporal resolution BC data since 2002 are necessary to investigate the impact of global

527   warming on boreal forest fires. Furthermore, high temporal resolution records of BC concentrations and sizes during the early

528   Holocene and the last interglacial period when it was warmer than the present day (NEEM community members, 2013; Vinther

529   et al., 2009) should be obtained for better projections of BC–climate interactions in a future warming world.

530

531   **Data availability**

532   All the data used in this study will be submitted to the Arctic Data Archive System (ADS) as soon as the manuscript has been

533   published.

534

535   **Author contributions**

536   KGA designed the study and led the manuscript writing. YOT was responsible for the BC measurements. YOT, MH, RD, and

537   JO performed the CFA analyses of the SIGMA-D core. MH and SM measured the ion concentrations in the discrete samples.

538   KGA, YOT, and KaF analysed the data. KGA, YOT, NM, TM, SO, YK, and MK interpreted the BC data. KoF performed

539   backward trajectory analyses. TA designed and led the ice coring project at SIGMA-D. TA computed the impacts of BC on

540   albedo. All the authors discussed the results.
